If You Have a Reliable Source, Say Something: 
Effects of Correction Comments on COVID-19 Misinformation

Haeseung Seo, Aiping Xiong, Sian Lee, Dongwon Lee

Abstract
In the post-truth era, particularly during the COVID-19 pandemic, an effective correction on misinformation is necessary to promote personal and public health. To better understand the effect of “correcting” misinformation, therefore, we investigated correction from different users on social media (e.g., individual users, fact-checking websites, and health organizations) and the frequency of correction (e.g., once vs. twice) in three online experiments. In each experiment, we evaluated participants’ perceived accuracy and willingness to share in terms of real and fake news of COVID-19, respectively. Across all experiments, a single correction from the health organizations effectively reduced participants’ perceived accuracy rating on the COVID-19 fake news. Experiments 2 and 3 revealed the effects of a single correction from individual users and fact-checking websites. Moreover, results of post-session questionnaires indicated that participants counted on the reliability of the sources in the correction. We did not obtain the consistent effects of frequent correction but verified the vulnerability of participants with high health anxiety to the COVID-19 fake news across all experiments. Overall, our study highlights the effects of user-initiated correction regardless of whether the user is an individual or an organization, as long as the correction contains a reliable source.

Introduction
The explosion of fake news is one of the problems that social media has triggered (Ha, Andreu Perez, and Ray 2021). On social media platforms, people can easily get and share news even before checking its veracity. Thus, platforms such as Twitter and Facebook have attempted to contrive ways to curtail misinformation, such as computationally detecting fake news (Facebook 2020) or correcting misinformation (Roth and Pickles 2021). The focus of our work is on the latter.

Despite considerable research on correcting misinformation (Vraga and Bode 2017; Bode and Vraga 2018; Pennycook, Cannon, and Rand 2018; Seo, Xiong, and Lee 2019; Seo et al. 2021), it is still premature to conclude the most effective way to correct misinformation. In addition to the methods to correct misinformation by platforms (e.g., the popping-up warning message for questionable contents), research on user-initiated correction has started recently (Vraga and Bode 2017, 2018). It is critical to investigate effective user-initiated methods to correct misinformation as users are the main characters sharing information on social media. Moreover, prior studies demonstrated that users have actively participated in the corrections on social media (Bode and Vraga 2021).

During the COVID-19 pandemic, a great deal of misinformation about the virus and treatments has been pouring out on social media, threatening personal and public health worldwide. In reality, there were many cases where people died from wrong treatments for COVID-19 due to fake news.1 Since people with high health anxiety are more associated with seeking online health information (Starcevic and Berle 2013; McMullan et al. 2019), they can be more vulnerable to COVID-19 misinformation and more resistant to the correction compared to people with low health anxiety. Therefore, it is imperative to examine the effective correction on COVID-19 misinformation, and understand how people’s health anxiety level impacts the correction effects.

Focusing on the correction on COVID-19 misinformation, we investigated the following research questions (RQs) in current work.

- **RQ 1.** Will the correction from an individual user or an organization user (e.g., a health organization or a fact-checking website) reduce participants’ susceptibility to fake news relative to a control condition in which there is no correction?

- **RQ 2.** Will more frequent correction reduce participants’ susceptibility to fake news more?

- **RQ 3.** Will people’s health anxiety level have an impact on their susceptibility to misinformation and the effect of misinformation correction?

We conducted three online experiments \((N = 2,841)\) on Amazon Mechanical Turk, examining correction from three types of users (e.g., health organizations, fact-checking websites, and individual users) \((RQ1)\). We verified that correction from all three types of users could reduce participants’ perceived accuracy rating on the COVID-19 fake news. Critically, we unearthed that participants counted on the reliability of the sources (e.g., social media users or URLs in the correction). We did not obtain the frequency effect \((RQ2)\). However, we discovered that participants having high health anxiety were more likely to believe fake news than low anxiety participants. We also obtained evidence showing the correction effect only for participants with low health anxiety. Those results imply that people with high health anxiety are more susceptible to the COVID-19 misinformation and more resistant to the misinformation correction \((RQ3)\).

---

To the best of our knowledge, the current paper is the first to experimentally investigate the effective user-initiated correction on COVID-19 misinformation. Our experiments improve the understanding of user-initiated correction on misinformation through the following contributions.

• Via systematically-designed experiments, we obtained correction effect on fake news from three different types of users: individual users, health organizations, and fact-checking websites.

• We unearthed that people weigh the reliable sources in correction the most when deciding perceived accuracy rating.

• We found that individuals with high health anxiety are more susceptible to health-related misinformation than those with low health anxiety and correction can work better for individuals with low health anxiety.

**Related Work**

**Misinformation**

Despite many definitions, the term “misinformation” generally refers to falsely fabricated information regardless of whether it includes intent to mislead (Cook, Ecker, and Lewandowsky 2015; Ha, Andreu Perez, and Ray 2021). According to one of the commonly used definitions, it indicates information without clear evidence and expert opinion (Nyhan and Reifler 2010; Vraga and Bode 2017). Meanwhile, “fake news,” as a type of misinformation (Lazer et al. 2018), has begun to attract the public’s attention with the growth of social media and mobile media since 2008, and have become popularized around the world since the 2016 U.S. presidential election (Quandt et al. 2019). In this work, we call interchangeably false information on social media either misinformation or fake news.

**Misinformation and Correction**

With the dissemination of misinformation online, researchers are increasingly interested in correcting misinformation (Seifert 2002; Nyhan and Reifler 2010; Gordon and Shapiro 2012; Cook, Ecker, and Lewandowsky 2015; Thorson 2016; Ha, Andreu Perez, and Ray 2021). Nevertheless, empirical studies revealed mixed results on the effect of correction (Walter and Murphy 2018). While some studies showed that correction can significantly reduce participants’ misinformation belief (Vraga and Bode 2017; Bode and Vraga 2018), the other studies showed negative effects such as backfire (Nyhan and Reifler 2010; Mosleh et al. 2021), or combined effects simultaneously (Nyhan and Reifler 2015; Jiang and Wilson 2018).

Lewandowsky and his colleagues analyzed the reasons for failure of misinformation correction comprehensively from a psychological perspective and suggested solutions, such as alternative account, emphasis on facts, and simple rebuttal (Lewandowsky et al. 2012). Walter and Murphy (2018) conducted a meta-analysis of empirical studies and categorized promising ways of correction, including source credibility, fact-checking, and providing general warnings.

Due to the proliferation of misinformation on social media (Allcott and Gentzkow 2017), recent studies on correction effects have mainly centered on platforms such as Twitter and Facebook. Depending on who initiated the correction, we can divide those studies into two approaches: platform-driven correction and user-initiated correction.

**Platform-driven Correction.** Studies of platform-driven correction evaluated corrections, including fact-checking warnings (Pennycook, Cannon, and Rand 2018; Seo, Xiong, and Lee 2019) or related articles (Smith and Seitz 2019). Due to the inclusion of news sources, the effect of platform-driven corrections was somewhat inconclusive (Smith and Seitz 2019). After controlling the news source, Seo, Xiong, and Lee (2019) found that the effect of fact-checking warning became non-significantly different from a control condition. Moreover, the effect of platform-driven corrections may also be impacted by the public’s increasing distrust of social media platforms due to events such as personal information leakage or excessive control over information.

**User-initiated Correction.** Since users are the main actors of information sharing on social media (Boydo and Eliison 2007; Bechmann and Lomborg 2013), the other approach concentrates upon user-initiated correction using user comments or posts (Vraga and Bode 2017; Gesser-Edelsburg et al. 2018). Vraga and Bode investigated the effect of user-initiated correction on Zika virus misinformation using users’ comments on social media (Vraga and Bode 2017, 2018; Bode and Vraga 2018). They manipulated one post within a simulated Twitter or Facebook feed. In the control condition, there was no misinformation. In the treatment conditions, a piece of fake news about the Zika outbreak in the U.S. was presented, with the image and the headline claiming that the outbreak was caused by the release of GMO mosquitoes. Following misinformation, a debunking sentence with a reference link from the Centers for Disease Control and Prevention (CDC) was presented. Across conditions, the source of correcting comments was varied from an organization (e.g., CDC), an individual, or both.

They recruited undergraduate students and measured participants’ misperception about the Zika virus before and after the correction of misinformation. Across studies, they demonstrated that social correction could work if it includes sufficient source information, including organization logos (such as snopes.com and CDC) and reference links from the organizations. Their results also revealed that platforms (Facebook or Twitter) did not matter (Vraga and Bode 2018) and social and algorithmic corrections were equally effective in mitigating misperceptions (Bode and Vraga 2018). One of their studies found the correction effect from a reputable organization (e.g., CDC) but not from an individual user (Vraga and Bode 2017).

Moreover, recent work showed that people experience both misinformation and its correction on social media. Bode and Vraga (2021) conducted an online survey about people’s correction experience regarding COVID-19 misinformation, showing that people are more likely to trust corrections when they come from reputable sources. But empirical studies also revealed that the effect of correction was partially alleviated by the public’s distrust in social media, which was affected by the reputation of the posting platform.

<http://tiny.cc/at1juz;http://tiny.cc/zugxtz;http://tiny.cc/1vgxtz>
formation on social media. Out of 1,094 participants, 34% witnessed that others’ wrong beliefs were corrected and 22% corrected others’ misinformation, demonstrating users’ active participation in correction. Given the impacts of user-initiative comments, it is critical to examine the effective correction in the setting of COVID-19. In our current work, we evaluated a single correction comment initiated by different social media users (e.g., an organization user or an individual user) with a more structured experimental design using COVID-19 news.

Health Anxiety

Besides an innumerable amount of COVID-19 fake news being spread online (Tasnim, Hossain, and Mazumder 2020), many cases related to health anxiety (i.e., hypochondria) and mental health issues have been reported during COVID-19 pandemic (Jungmann and Witthöft 2020). Prior studies (Asmundson and Taylor 2020; Banerjee, Rao et al. 2020) explain abnormally increased fear and anxiety for health as one reason for information seeking about the COVID-19, which is also called “Cyberchondria” (McMullan et al. 2019; Laato et al. 2020). Considering the health news topic, we also measured participants’ health anxiety (Lucock and Morley 1996) and analyzed its impact on the effect of correction for COVID-19 misinformation.

The Present Study

We investigated a single user-initiated correction comment using tweets format in three online experiments. In contrast to prior works (Bode and Vraga 2015; Vraga and Bode 2017), we recruited Amazon Mechanical Turk (MTurk) workers who are more demographically diverse (Berinsky, Huber, and Lenz 2012; Briones and Benham 2017; Weigold and Weigold 2021) than college students. In each experiment, participants evaluated eight to twelve pieces of fake and real news about COVID-19 instead of evaluating a single piece of misinformation. We examined the effect of correction comments on people’s acceptance of fake news about COVID-19 compared to a control in which comments without correction were presented, rather than examining the correction effect by comparing participants’ pre- and post-perception of misinformation (Vraga and Bode 2017).

We examined COVID-19 misinformation, which is most timely. Moreover, we ran our experiments at three different time points over six months during the COVID-19 pandemic. We updated the evaluated news set from Experiment 2 to reflect the rapidly pouring news. We proposed and evaluated different types of users on social media (e.g., individual users, health organizations, and fact-checking websites).

Experiment 1 examined the effect of a single correction comment about COVID-19 fake news by individual users or organization users. Experiment 2 was conducted to replicate the findings of Experiment 1 using a new set of COVID-19 real and fake news. Experiment 3 increased the types of correction to be investigated for a more systematic understanding of the correction effect.

Figure 1: An example of COVID fake news stimuli across the three between-subject conditions composed of an image, a headline, and a snippet of the news article shown under a message tweeting the fake news. Following the tweet, a comment was presented. The comment sentences of hORG and hIND are the same, correcting the tweet by indicating the falsity of the fake news with an identical reference link from a health organization (CDC or WHO). CON has a comment without a correction message or a reference link.

Experiment 1

Using a between-subject design, we investigated the effect of correction comments on COVID-19 misinformation across three conditions: no correction (CON), correction by an individual user (hIND), and correction by a health organization (hORG). Specifically, fake news stimuli of hIND and hORG had the same correcting comment, including a reference link from a health organization. “h” indicates the identical link from health organizations (CDC or WHO). Moreover, to investigate the frequency effect of correction, we composed Phases 1 and 2. Half of the fake and real news of Phase 1 were presented again at Phase 2, each of which was with a similar correcting comment but from a different user and a different organizational source.

Participants

In this and the following experiments, we recruited participants by posting the Human Intelligent Task (HIT) on MTurk. We restricted the workers to those who (1) were at least 18 years old; (2) were located in the U.S.; and (3) completed more than 100 HITs with a HIT approval rate of at least 95%. Qualtrics was used to program our online studies. Our study was approved by the institutional review board (IRB) office at our institution.

Materials

We selected eight news articles about COVID-19 released between March and May 2020 from snopes.com or poli-
tfact.com, both of which are well-regarded fact-checking websites. Four pieces of the news were fake and the other four pieces were real. Also, we used another piece of real news for an attention check (Hauser and Schwarz 2016).

As shown in Figure 1, we created a simulated Twitter interface, in which each piece of news was embedded within a tweet message. For each stimulus, a tweet message from a fictional user was presented above the COVID-19 news. The tweet message was a short sentence related to the news without any correcting message. The embedded news was composed of an image, a headline, and a snippet of the news article. Following the news article, a comment from another user was presented.

For the fake news, each comment in the hIND and hORG conditions included a sentence pointing out the falsity of the fake news articles with a reference link from an authoritative organization (CDC for Phase 1, WHO for Phase 2). The correction messages and the reference links were the same between hORG and hIND.

In contrast, each comment of the fake news in CON did not contain a correcting sentence or reference link. Instead, the comment included a commenter’s plausible but non-correcting messages varied according to the contents of each piece of news. Likewise, the real news comments had non-correcting messages, which were constructed in the same way as the fake news in CON. We used the same set of real news and its comments across the three conditions.

When we presented half of the stimuli again at Phase 2, we varied the user of the comment for both fake and real news regardless of conditions. Furthermore, we presented a different reference link for fake news of hORG and hIND at Phase 2 (e.g., the comment from CDC and a reference link, cdc.gov/coronavirus, in Phase 1, the comment from World Health Organization (WHO) and a reference link, who.int/coronavirus, in Phase 2). The expressions of comments at both phases conveyed the same content but with some wording changes. All authors reached a consensus on the contents of all messages we used for experiments.

Procedure

Figure 2 illustrates the flow chart of Experiment 1. Participants were randomly assigned to one of three conditions. After participants provided informed consent, Phase 1 started, in which the eight pieces of stimuli were presented in a randomized order. Half of them included fake news and the other half included real news. We asked two questions to examine participant’s susceptibility to the “claim” embedded in the news article of each stimulus. First, participants answered, “How accurate is the claim in the above news?” on a 7-point scale with “1” meaning “Very inaccurate” and “7” meaning “Very accurate.” Then they rated their willingness to share the news by answering, “Would you consider sharing this news online (for example, through Facebook or Twitter)?” using another 7-point scale with “1” meaning “Never” and “7” meaning “Always.”

Following Phase 1, two pieces of the real news stimuli and two pieces of the fake news stimuli were presented once more in a randomized order at Phase 2 to investigate the effect of correction frequency. We used a semi Latin-square design for a better-balanced assignment of news shown at Phase 2. Participants answered the same two questions for each piece of stimuli as Phase 1.

After Phase 2, there was a post-session questionnaire. Participants first filled in their demographic information, including age, gender, ethnicity, and education. Then we measured participants’ health anxiety level using four representative questions (Lucock and Morley 1996). A 5-point scale with “1” meaning “None at all” and “5” meaning “A great deal” was used for the first two questions: 1) “How much do you usually worry about your health?” and 2) “How much are you ever worried that you may get a serious illness in the future?” Another 5-point scale with “1” meaning “Rarely” and “5” meaning “Usually” was used for the latter two questions: 3) “How often do you tend to read up about illness and disease to see if you may be suffering from one?” and 4) “How often do your bodily symptoms stop you from concentrating on what you are doing?” Participants were allowed to choose “Prefer not to answer” for all post-session questionnaires except for age.

An extra piece of real news was included at Phase 1 to exclude inattentive participants. We presented specific instructions about how to answer the attention-check question to the participants. For any participants who failed to follow the instruction, their survey was terminated immediately.

Results

We recruited 1,275 MTurk workers in July 2020. We accepted 907 participants’ answers after removing five responses submitted out of the U.S., two responses submitted within two minutes (median completion time was about six minutes), 103 responses who failed an attention check, and
258 duplicated submissions. The numbers of participants of the three conditions included in the data analysis are as follows: 295 (CON), 305 (hORG), and 307 (hIND). We paid $0.75 for participants who completed the task based on an hourly payment of $7.5. Participants’ demographic information is shown in Table 1.

For data analysis, we used three levels of news frequency: ONCE (Phase 1 results of news shown at Phase 1 only), TWO1st (Phase 1 results of news shown at both phases), and TWO2nd (Phase 2 results of news shown at both phases).

Perceived accuracy rating and willingness-to-share measures were entered into 3 (condition: CON, hORG, hIND) × 2 (veracity: fake, real) × 2 (frequency: ONCE, TWO2nd) mixed analysis of variances (ANOVA) (Herzog, Francis, and Clarke 2019) with a significance level of .05, respectively. Post-hoc tests with Bonferroni correction were performed. We report the effect size using $\eta^2_p$ reported by SPSS (Ecker, Lewandowsky, and Apai 2011; Vraga and Bode 2017).

To understand the frequency effect, we also analyzed the results between ONCE and TWO1st, and between TWO1st and TWO2nd. Across the three experiments, the analysis results did not show any significant difference between ONCE and TWO1st. Also, the results of the analysis between TWO1st and TWO2nd showed similar patterns and had only marginal differences compared to the results between ONCE and TWO2nd. Thus, we evaluated the main analysis between ONCE and TWO2nd in this and the following experiments.

Figure 3: The average values of perceived accuracy ratings as a function of frequency × condition for real news (left panel) and fake news (right panel) with one standard error.

**Perceived Accuracy Rating.** Results of average the perceived accuracy rating are shown in Figure 3. Participants clearly distinguished real news (5.15) from fake news (2.55), $F(1,904)^5 = 1914.98$, $p < .001$, $\eta^2_p = .679$. The two-way interaction of news veracity × condition was also significant, $F(2,904) = 12.85$, $p < .001$, $\eta^2_p = .028$. Post-hoc tests revealed that the effect of condition was significant for both fake news, $F(2,904) = 6.69$, $p = .001$, $\eta^2_p = .014$, and real news, $F(2,904) = 4.29$, $p = .014$, $\eta^2_p = .009$. Nevertheless, the effect of condition revealed different patterns. For fake news, only participants in the hORG condition (2.27) gave lower accuracy ratings relative to the CON condition (2.79), $p_{adj} = .001$. The other two pairwise comparisons (i.e., CON vs. hIND (2.58), $p_{adj} = .427$, and hORG vs. hIND, $p_{adj} = .090$) were not significant. For real news, relative to CON (5.01), participants gave higher accuracy ratings for both hORG (5.22), $p_{adj} = .029$, and hIND (5.22), $p_{adj} = .039$. However, the perceived accuracy ratings between hORG and hIND conditions were not significantly different, $p_{adj} > .999$.

Thus, we obtained the correction effect of comment from an organization user for COVID-19 fake news, which is in agreement with the prior work about Zika virus misinformation (Vraga and Bode 2017). Also, we found the positive impact of the news correction on real news.

**Sharing Decisions.** Results of willingness-to-share real and fake news are presented in Figure 4. Participants’ willingness to share real news (3.68) was higher than that of fake news (2.35), $F(1,904) = 708.13$, $p < .001$, $\eta^2_p = .439$. The interaction between veracity × condition only showed a trend to be significant, $F(2,904) = 2.87$, $p = .057$, $\eta^2_p = .006$. Moreover, participants’ overall rating for the willingness-to-share measure (real: 3.68, fake: 2.35) was lower than that of the perceived accuracy rate (real: 5.15, fake: 2.55), indicating that they tended to be conservative in sharing decisions than perceived accuracy evaluation.

**Health Anxiety.** We calculated a mean score of the four questions about health anxiety for COVID-19 participants after removing the results of two participants who refused to answer all of the questions (CON:294, hORG:305, hIND:306). We then classified the

---

4We are aware of $\eta^2_p$, which was recommended to report (Bakeman 2005; Lakens 2013) considering factors manipulated and measured between subjects (Olejnik and Algina 2003). To make the results comparable to the literature (Vraga and Bode 2017), we report the $\eta^2_p$ to show the effect size based on SPSS analysis.

5$F$ value equals to variance estimate based on variability among group means divided by variance estimate based on variability within groups. Hence, the larger $F$ value indicates that the variability in the measurements is mostly determined by the group differences (Herzog, Francis, and Clarke 2019).
results into two groups: low health anxiety (scores from 1 to 2) and high health anxiety (scores from 3 to 5). For the statistical tests, we added health anxiety as an additional between-subject factor into the main analysis. For perceived accuracy rating, participants with high health anxiety (4.30) gave a higher accuracy rating than those with low health anxiety (3.58), $F(1,899) = 93.24, p < .001, \eta^2_p = .094$, and its interaction with veracity, $F(1,899) = 71.67, p < .001, \eta^2_p = .074$, were significant. The effect of health anxiety was more evident for the fake news (high health anxiety: 3.28; low health anxiety: 2.09), $F(1,903) = 104.84, p < .001, \eta^2_p = .104$ than for the real news (high health anxiety: 5.29; low health anxiety: 5.06), $F(1,903) = 10.99, p < .001, \eta^2_p = .012$.

Likewise, participants with high health anxiety (3.78) showed more willingness to share news than those with low health anxiety (2.57), $F(1,899) = 125.79, p < .001, \eta^2_p = .123$. The two-way interaction of veracity $\times$ health anxiety was also significant, $F(1,899) = 9.76, p = .002, \eta^2_p = .011$. The effect of health anxiety was also more evident for the fake news (high health anxiety: 3.19; low health anxiety: 1.84), $F(1,903) = 124.00, p < .001, \eta^2_p = .121$, than for the real news (high health anxiety: 4.33; low health anxiety: 3.29), $F(1,903) = 78.45, p < .001, \eta^2_p = .080$.

We also obtained a four-way interaction of veracity $\times$ condition $\times$ health, $F(2,899) = 3.13, p = .044, \eta^2_p = .007$. The post-hoc test presented that it was mainly due to a non-significant trend of correction effect on fake news for the low health anxiety group, $F(2,557) = 2.81, p = .061, \eta^2_p = .010$, suggesting the misinformation susceptibility of people with high health anxiety was somewhat difficult to mitigate.

### Summary

In Experiment 1, we examined the effects of correcting comments from health organizations (hORG) and individual users (hIND) (RQ1), as well as the effect of correction frequency (RQ2) in helping users mitigate fake news. Consequently, we verified the effect of correction from a health organization (hORG) for reducing perceived accuracy rating on fake news as in the prior study (Vraga and Bode 2017) but did not find a frequency effect. Furthermore, we discovered perceived accuracy rating of real news was higher given correction compared to CON, which indicates correction increased participants’ confidence in real news through learning effects from the correction on fake news.

In addition, we found that participants with high health anxiety were more susceptible to COVID-19 misinformation than those with low health anxiety (RQ3): People with high health anxiety gave higher perceived accuracy ratings and were more willing to share health-related news than those with low health anxiety; and such pattern was more evident for the fake news than for the real news.

### Experiment 2

To replicate the findings of Experiment 1, we conducted Experiment 2 with up-to-date COVID-19 news articles released from May to July 2020. The experimental setting was the same as Experiment 1 except as noted. We created twelve stimuli, half about fake news and the other half about real news, on the simulated Twitter interface of Experiment 1. The attention check was between Phases 1 and 2. We added two political-stance related questions in the post-session questions due to the impact of political ideology on people’s susceptibility to COVID-19 misinformation (Calvillo et al. 2020). Moreover, we included follow-up questions to identify which factors among the given stimuli influenced participants’ perceived accuracy rating.

### Results

We recruited 1,255 MTurk workers in December 2020. We accepted 768 participants’ answers after removing two responses submitted out of the U.S., 291 who failed an attention check, 186 duplicated submissions, and eight responses submitted out of the U.S., 291 who failed an attention check and completed the task. The payment rate ($7.5/hr) is the same as Experiment 1. Participants’ demographic information is shown in Table 1. We analyzed the data in the same way as Experiment 1.

### Perceived Accuracy Rating

Average results of the real and fake news for each condition are shown in Figure 5. The main effects of news veracity, $F(1,765) = 1411.78, p < .001, \eta^2_p = .649$, condition, $F(2,765) = 4.15, p = .016, \eta^2_p = .011$, as well as the two-way interaction of news veracity $\times$ condition, $F(2,765) = 17.53, p < .001, \eta^2_p = .044$, were significant. Same as in Experiment 1, participants can distinguish real news (4.91) from fake news (2.71). Post-hoc analysis
Figure 6: The average values of willingness-to-share as a function of frequency × condition for real news (left panel) and fake news (right panel) with one standard error.

revealed that the perceived accuracy ratings across the conditions were similar for real news but different for fake news. Compared to CON (3.11), lower accuracy rating was evident for fake news at hORG (2.48), $p_{adj} < .001$, and hIND (2.55), $p_{adj} < .001$, respectively. Thus, the correction effect was evident for both hORG and hIND conditions. In addition, there was a three-way interaction of veracity × frequency × conditions, $F_{(2,765)} = 3.45, p = .032, \eta_p^2 = .009$, showing decreased perceived accuracy rating for fake news from ONCE to TWO2nd in hORG (2.54 → 2.41) and hIND (2.59 → 2.50) but not in CON (3.10 → 3.11).

**Sharing Decisions.** Results of willingness-to-share measure are presented in Figure 6. Participants showed more willingness to share real news (3.41) than fake news (2.34), $F_{(1,765)} = 480.27$, $p < .001, \eta_p^2 = .386$. The interaction of veracity × condition was significant, $F_{(2,765)} = 8.25, p < .001, \eta_p^2 = .021$. The main effect of condition was not significant at each veracity level. However, participants’ willingness-to-share for the hORG and hIND conditions showed a trend to be larger than that of CON for the real news, while an opposite pattern was revealed for fake news.

Moreover, the two-way interaction of veracity × frequency approached significance, $F_{(1,765)} = 3.76, p = .053, \eta_p^2 = .005$, suggesting an increase of willingness to share for real news but a decreasing trend for fake news from ONCE to TWO2nd. As in Experiment 1, the average of willingness-to-share measure was lower than that of perceived accuracy rating, indicating that participants tended to be conservative in sharing news regardless of news accuracy.

**Health Anxiety.** After removing the results of three participants who did not complete the questions, we analyzed 765 (CON:251, hORG:261, hIND:253) participants’ results by adding health anxiety in the main analyses. For perceived accuracy rating, participants with high health anxiety (4.09) gave a higher accuracy rating than those with low health anxiety (3.63), $F_{(1,759)} = 37.62, p < .001, \eta_p^2 = .047$. And its interaction with veracity, $F_{(1,759)} = 7.41, p = .007, \eta_p^2 = .010$ was also significant. As in Experiment 1, the effect of health anxiety was more evident for the fake news (high health anxiety: 3.09; low health anxiety: 2.46), $F_{(1,763)} = 28.07, p < .001, \eta_p^2 = .035$, than for the real news (high health anxiety: 5.10; low health anxiety: 4.80), $F_{(1,763)} = 18.73, p < .001, \eta_p^2 = .024$. Moreover, the three-way interaction of veracity × condition × health anxiety was significant, $F_{(1,759)} = 3.38, p = .034, \eta_p^2 = .009$. Post-hoc comparison showed that the correction on fake news turned out to be effective for participants with low health anxiety in the hORG (2.09), $p_{adj} < .001$, and the hIND (2.27), $p_{adj} < .001$, than those in the CON (3.03), respectively.

Participants with high health anxiety (3.44) gave higher willingness-to-share score than those with low health anxiety (2.51), $F_{(1,759)} = 67.99, p < .001, \eta_p^2 = .082$. Thus, people who are highly anxious about their health tended to share more health-related news regardless of news veracity.

**Political Stance.** At the post-session questions, we also measured participants’ political stance with a 5-point scale (“1” meaning “very liberal,” “5” meaning “very conservative”). Participants who gave a rating of “1” or “2” were categorized as liberals (336), and those who gave a rating of “4” or “5” were categorized as conservatives (228). We excluded moderates (204), i.e., who gave a rating of “3” from the data analysis. We added political stance (liberals, conservatives) as another factor into ANOVAs of perceived accuracy rating and willingness-to-share measure, respectively.

For both perceived accuracy rating and willingness-to-share measure, the main effect of political stance, $F_{(1,558)} = 52.89$ and 30.50, $ps < .001, \eta_p^2 = .087$ and .052, and its interaction with veracity, $F_{(1,558)} = 135.63$ and 65.09, $ps < .001, \eta_p^2 = .196$ and .104, were significant. Specifically, for perceived accuracy rating, the effect of political stance was only significant for the fake news (liberals: 2.18, conservatives: 3.58), $F_{(1,562)} = 108.85, p < .001, \eta_p^2 = .162$, but not for the real news (liberals: 5.0, conservatives: 4.91), $F_{(1,562)} = 1.306, p = .254, \eta_p^2 = .002$. For the willingness-to-share measure, the effect of political stance was more evident for the fake news (liberals:1.90, conservatives: 3.12), $F_{(1,562)} = 66.94, p < .001, \eta_p^2 = .106$, than for the real news (liberals:3.32, conservatives: 3.65), $F_{(1,562)} = 4.84, p = .028, \eta_p^2 = .009$.

Yet, we did not obtain the three-way interaction of political stance × veracity × condition for perceived accuracy rating or willingness-to-share measure, $F_{(1,558)} = 2.18$ and 1.82, $ps = .114$ and .162, $\eta_p^2 = .008$ and .006, indicating minimal impacts of correction on addressing conservatives’ higher susceptibility to COVID-19 misinformation.

**Influential Factors.** In the post-session question, we also asked participants to specify factors that impacted their perceived accuracy rating, including “user tweet (text),” “users tweet (image),” “comments,” and “other.” For participants who selected “comments,” we further asked them to select the parts of comments affected their decision the most among the options “who wrote the comment,” “how persuasively the comment was written,” “whether the comment included a reference URL,” and “other.”

As shown in Figure 7 top panel, the majority of the participants chose “other’s comments” as the most influential factors, and the results were similar between hORG (36%) and hIND (33.9%). For participants who chose “comment,” those in the hORG condition chose “who wrote” the most (67.6%) while those in the hIND condition chose “URL” the most (49.6%), $\chi^2(3) = 103.54, p < .001$, revealing the influence of reliable sources.
Summary

In Experiment 2, we not only replicated the effects of a correcting comment from health organizations (hORG) but also verified the correction effect from individual users (hIND). Both hORG and hIND reduced perceived accuracy rating on fake news (RQ1). Moreover, we obtained that participants relied on reliable sources of correcting comments. Specifically, hORG valued “who wrote the comment” the most while hIND valued “URL” the most. We also obtained evidence of the frequency effect showing decreased perceived accuracy rating for the fake news at Phase 2 (RQ2). Meanwhile, we found both hORG and hIND were effective for the low anxiety group to reduce their perceived accuracy rating on fake news (RQ3).

Experiment 3

Besides health organizations, fact-checking websites investigated false claims about COVID-19 from the beginning of the pandemic (Brennen et al. 2020). Thus, we ran Experiment 3 not only to verify again the correction effects of existing conditions (hORG, hIND), but also to examine the correction effects with two new conditions that are relevant to fact-checking websites (fcORG, fcIND, where “fc” indicates fact-checking websites). All experiment designs and news contents were the same as Experiment 2 except as noted. fcORG condition included correction from a fact-checking website with a reference link from the site, fcIND condition included the identical reference link as the fcORG condition but the correction was from an individual user. Regarding frequency effect, for both the fcORG and fcIND conditions, the link of snopes.com was used for the correction at Phase 1, and the link of politifact.com was used for the correction at Phase 2.

Results

We recruited 2,060 MTurk workers from November to December, 2020. We accepted 1,166 participants’ answers after removing one incomplete submission, four responses submitted out of the U.S., 406 who failed an attention check, 473 duplicated submissions, and ten responses submitted less than three minutes (median completion time is about 10 minutes). The number of participants for each condition is as follows: 250 (CON), 236 (hORG), 227 (hIND), 214 (fcORG), and 239 (fcIND). The payment was the same as Experiment 2. Participants’ demographic information is as Table 1.

Perceived accuracy rating and willingness-to-share measure were entered into 5 (condition: CON, hORG, hIND, fcORG, fcIND) × 2 (veracity: fake, real) × 2 (frequency: ONE, TWO) mixed ANOVAs with a significance level of .05, respectively. Post-hoc tests with Bonferroni correction were performed.

Perceived Accuracy Rating. Results of perceived accuracy rating are shown in Figure 8. Same as prior two experiments, participants can distinguish real news (4.97) from fake news (2.95), 4.1161 = 1577.27, p < .001, η² = .576. The main effect of condition was also significant, 4.1161 = 3.76, p = .005, η² = .013, and the difference among conditions was qualified by the effect of news veracity, 4.1161 = 12.59, p < .001, η² = .042. Same as Experiment 2, post-hoc tests revealed that the effect of each treatment condition was significant for the fake news compared to CON, p_{adj.} < .001.

Sharing Decisions. Results of willingness-to-share measure are presented in Figure 9. Participants showed more willingness to share real news (3.71) than fake news (2.66), 4.1161 = 605.38, p < .001, η² = .343. Also, the interaction of veracity × condition was significant, 4.1161 = 4.32, p = .002, η² = .015. In the post-hoc comparisons, only the gap between fcIND and CON for fake news was significant, p_{adj.} = .033.
**Health Anxiety.** We analyzed 1166 participants’ results as in previous experiments. For perceived accuracy rating, participants with high health anxiety (4.32) gave a higher accuracy rating than those with low health anxiety (3.72), $F(1,1156) = 84.42$, $p < .001$, $\eta_p^2 = .068$, and such pattern was more evident for fake news (high health anxiety: 3.45; low health anxiety: 2.63), $F(1,1164) = 67.58$, $p < .001$, $\eta_p^2 = .051$ than for real news (high health anxiety: 5.20; low health anxiety: 4.82), $F(1,1164) = 41.63$, $p < .001$, $\eta_p^2 = .035$.

For willingness-to-share, participants with high health anxiety (3.83) gave higher willingness-to-share score than those with low health anxiety (2.75), $F(1,1156) = 124.33$, $p < .001$, $\eta_p^2 = .097$, similar to Experiments 1 and 2. Thus, highly anxious people about their health tended to share more health-related news regardless of news veracity.

**Political Stance.** We analyzed the effect of political stance as in Experiment 2 with 464 of liberals and 377 of conservatives after removing 325 moderates. The main effect of political stance, $F(1,831) = 24.53$ and 17.95, $ps < .001$, $\eta_p^2 = .029$ and .021, and its interaction with veracity, $F(1,831) = 161.99$ and 80.38, $ps < .001$, $\eta_p^2 = .163$ and .088, were significant for both perceived accuracy rating and willingness-to-share measure. Specifically, for perceived accuracy rating, the effect of political stance was more evident for the fake news (liberals: 2.58, conservatives: 3.73), $F(1,839) = 86.07$, $p < .001$, $\eta_p^2 = .093$, than for the real news (liberals: 5.16, conservatives: 4.83), $F(1,839) = 22.61$, $p < .001$, $\eta_p^2 = .026$. For the willingness-to-share measure, the effect of political stance was only significant for the fake news (liberals:2.37, conservatives: 3.33), $F(1,831) = 48.54$, $p < .001$, $\eta_p^2 = .055$, but not the real news (liberals:3.75, conservatives: 3.82).

As in Experiment 2, conservatives were more susceptible to COVID-19 misinformation than liberals (Uscinski et al. 2020). However, we again did not obtain the three-way interaction of political stance × veracity × condition for neither measures, $F < 1.0$, showing limited impacts of correction on mitigating conservatives’ higher susceptibility to misinformation as Experiment 2.

**Influential Factors.** As in Experiment 2, we asked participants which factors were influential for their decision-making and which parts of comments influenced the most. Across all treatment conditions, participants chose “other’s comments” the most except for those in the $hIND$ condition (see Figure 10 top panel). For the following question asking the most influential part in the comments, participants in both organization conditions chose “who wrote” the most while those in both individual conditions chose “URL” the most, $\chi^2(9) = 145.80$, $p < .001$ (see Figure 10 bottom panel). Overall, the obtained results were consistent with those found in Experiment 2.

**Summary**

Findings of Experiment 3 were consistent with the previous two experiments. All types of corrections were effective in reducing participants’ perceived accuracy rating of fake news. We verified the effects of a correcting comment (RQ1) from fact-checking websites (fcORG) as well as the one from health organizations ($hORG$). Also, we found the effects of individual users’ correction which has a reference link from either fact-checking websites (fcIND) or health organizations ($hIND$). Moreover, we discovered that participants counted on the reliable source of a correcting comment. Specifically, participants in the $hORG$ and fcORG weighed “who wrote the comment” the most, while those in the $hIND$ and fcIND counted on “URL” the most. As in Experiment 1, we did not obtain the frequency effect (RQ2). Meanwhile, we found the minimal impacts of health anxiety or political stance on the correction effect (RQ3).

**General Discussion**

In the current study, we investigated if the correction from organization users or individual users can reduce participants’ susceptibility to COVID-19 fake news (RQ1). We also examined whether more frequent correction can further reduce the susceptibility (RQ2), and whether individuals’ health anxiety level has an impact on the effect of correction (RQ3). Across the three online experiments with 2, 841 participants, we examined the correction effects of three types of users on social media. We verified the effect of user-initiated correction in general, with the fact that participants counted on the reliability of correction. We also found that participants with high health anxiety were more susceptible to COVID-19 fake news than those with low health anxiety in all experiments.

**Effect of Correction from a Single User**

Previous work obtained the effect of user-initiated correction on social media by conducting a survey (Bode and Vraga 2021) or analyzing Twitter data (Jiang et al. 2020). Also, other studies (Vraga and Bode 2017, 2018) showed the effect of correcting comments in social media contexts by conducting experiments. Our study extended those works by demonstrating the consistent effects of user-initiated correction with reliable sources in reducing perceived accuracy
rating on COVID-19 fake news in a social media context.

We corroborated that people’s perceived accuracy rating on fake news could be reduced by a single correction comment by health organizations, fact-checking websites, or individual users. In particular, the correction effect was similar across different types of users. Critically, we unearthed that participants depended on the reliability of sources in the correction to decide their perceived accuracy rating. Participants in hORG and hIND chose “who wrote the comment” the most, while those in hIND and fIND chose “whether the comment included a reference URL” the most. The only difference between ORG and IND was whether the correction is directly delivered by reliable users or indirectly delivered through reliable URLs. Thus, our findings on the indirect effect of a reliable source contribute to the literature about the source effect (Vraga and Bode 2017; Seo, Xiong, and Lee 2019).

Although the hIND was effective on correction in Experiments 2 and 3, it did not show a significant difference compared to the no correction condition in Experiment 1. One possible explanation for the difference might be related to users’ increased knowledge about COVID-19 news (Bode and Vraga 2021), and consequently increased reliance on other individual users beyond health organizations to gain more information. The above reason may also explain the non-significant results of Vraga and Bode’s work (2017) since they implemented a relatively unfamiliar topic to the participants in their experiment. Moreover, across the three experiments, we found that participants’ perceived accuracy rating on real news in the treatment conditions was increased or similar to that in the control conditions, indicating limited side effects of user-initiated correction compared to platform-driven correction (e.g., fact-checking warnings) (Clayton et al. 2020).

In all experiments, participants were conservative in sharing news than the perceived accuracy rating, which may contribute to the minimal correction effect on misinformation sharing. Various motivations such as information-seeking, socializing, status-seeking, or prior social media sharing experience (Lee and Ma 2012) could drive people’s intention of news sharing on social media regardless of correction. Future studies could investigate effective correction to prevent misinformation sharing considering such motivations of sharing behaviors.

**Frequency Effect on Correction**

Throughout the experiments, the frequency effect on correction was only evident in Experiment 2. Results of Experiments 1 and 3 were consistent with the correction effect but did not show statistical significance: perceived accuracy rating and willingness-to-share measures were numerically smaller for the second correction than the first correction. Those results may be due to the use of the same comment messages across phases, since people typically expect varied comments from different social media users. Future work could consider varying correction messages to understand further the frequency effect of correction.

**Correction Effect Depending on Health Anxiety**

We discovered that participants with high health anxiety tended to believe and share more news regardless of news veracity than those with low health anxiety, indicating that the highly anxious people might seek reassurance through health information (Starcevic and Berle 2013). In particular, we verified that hORG and hIND were only effective for the low health anxiety group to reduce their perceived accuracy rating on fake news in Experiment 2. To our best knowledge, our study was the first dealing with the impact of health anxiety on correction for COVID-19 related fake news. Future studies should contrive correction methods, especially for people with high health anxiety, to mitigate their susceptibility to COVID-19 misinformation in particular and fake health news in general.

**Correction Effect Depending on Political Stance**

Experiments 2 and 3 revealed that conservatives were more susceptible to COVID-19 fake news than liberals. Such results are in agreement with a recent study showing stronger beliefs in COVID-19 fake news by conservatives (Uscinski et al. 2020). In both of our experiments, corrections showed minimal impacts on helping conservatives. Considering the impacts of political stance on various misinformation literature (Frenda et al. 2013; Benegal and Scruggs 2018; Pennycook and Rand 2019), we believe that further investigation on effective correction methods for more vulnerable populations (e.g., conservatives) is essential.

**Limitations and Future Work**

We discuss a few limitations that could be addressed in future studies. First, we chose MTurk for recruitment to gain a reasonably large sample size as previous misinformation studies did (Pennycook, Cannon, and Rand 2018; Clayton et al. 2020). MTurk workers are more demographically diverse than the college students (Briones and Benham 2017; Weigold and Weigold 2021). However, the MTurk population in general cannot fully represent the whole population. For instance, most MTurk workers tend to be in their 30’s (Burnham, Le, and Piedmont 2018). Therefore, a more comprehensive recruiting method could be used to generalize our findings to other samples in future studies. In addition, in terms of materials, we used a more recent news set in Experiments 2 and 3 since COVID-19 news has been quickly updated and diversified. This change seemed to lead to different average gaps of perceived accuracy ratings between real and fake news among experiments: Exp.1 (2.59), Exp.2 (2.20), Exp3 (2.02). Furthermore, it should be recognized that the effects found in our experiments may not appear in practice due to exclusion of other factors on social media (e.g., multiple replies and social relationships among users, etc.). Moreover, we are aware that participants could not pay attention to the correction in reality because of many distracting factors on social media, such as other postings and interactions with other users in real time. Also, we did not measure participants’ prior beliefs in the fake news. Therefore, we cannot rule out the possibility of having negative effects from correction (e.g., backfire effects) (Nyhan...
and Reifler 2010; Mosleh et al. 2021). Future works could develop experimental designs with more ecological validity and evaluate the generalizability of our findings.

Conclusion
In this work, we carried out three online experiments with a more systematic design to comprehend the impact of a single correction effect on reducing users’ fake news susceptibility on social media. In total, three types of users were investigated across the experiments. We verified the correction effects on reducing the user’s perceived accuracy ratings from individual users, health organizations, and fact-checking websites. Moreover, our study revealed that participants counted on the reliability of correction sources for their decision-making. We also found that high health anxiety people could be more susceptible to COVID-19 misinformation. Additionally, our results showed that conservatives are more susceptible to COVID-19 fake news than liberals. In conclusion, our findings highlight 1) the importance of encouraging social media users to leave correcting comments on fake news, as long as they have reliable sources, and 2) the necessity to develop effective correction methods considering individual differences (e.g., health anxiety level and political stance).

Ethical Statement
Our research protocol was approved by the Institutional Review Board (IRB) at The Pennsylvania State University. We asked for informed consent from participants. We made sure to take suitable steps in our data collection and analysis to ensure an ethical study and protect user privacy. Additionally, in order to avoid any issues of account or user identification and to protect user privacy, we did not name any accounts in this paper. In particular, we note that we did not debrief the participants. Several recent studies did the debriefing to minimize the impacts of misinformation over time (Murphy et al. 2020). Thus, we acknowledge that the lack of debriefing in our experiments could have potentially harmful effects on some participants (e.g., those in the control condition without misinformation correction). However, as a recent study revealed, misinformation study in general does not significantly increase participant’s long-term susceptibility to misinformation used in the experiments (Murphy et al. 2020).
